## Publisher Summary

This chapter outlines the way somatosensory cortical maps of the skin surface are determined experimentally and summarizes some of the evidence for the functional plasticity of these somatosensory cortical representations of the skin surface in adults. The chapter describes new electrophysiological results that demonstrate that there is a functional reorganization of cortical representations of the skin surfaces in the cortical zones surrounding focal cortical lesions and considers some implications of these experiments for understanding cortical mechanisms underlying the behavioral recovery following brain injury. Somatosensory cortical representations of the skin surfaces in monkeys are remodeled by use throughout life by intrinsic input selection processes. Those processes are thought to underly learning, memory, and the acquisition of skill. In

These processes are thought to underlie learning, memory, and the acquisition of skill. In any event, there is a manifest plasticity of functional representational detail driven by use in cortical area, 3b, operating over distances of hundreds of microns in normal adult primates. It has been concluded that this functional map alterability does not involve a significant growth or movement of input terminal arbors, but rather, is accounted for by changes in the effectiveness of anatomically static inputs.
