Abstract

• From Aug 6 to 14, 1973, scarlatiniform eruptions that were considered to be mild forms of the staphylococcal scalded-skin syndrome developed in four neonates. One infant had mild epidermal peeling. All had generalized, finely papular erythema that cleared rapidly after treatment with antibiotics.

Cultures from the umbilical stumps or anterior nares of three of the infants yielded colonies of group I *Staphylococcus aureus* phage type 29/52/79/86/D11/81

attached colonies of group I *Staphylococcus aureus*, phage type 25/32/75/33/21/31, that were able to produce epidermal exfoliation in suckling mice. These data indicate that the nursery outbreak was caused by phage group I staphylococci rather than group II organisms previously associated with staphylococcal scalded-skin syndrome. The demonstration that a group I *Staphylococcus* can produce exfoliative toxin suggests that the same mechanism for toxin production may exist for phage groups I and II staphylococci.
